**In situ** formation of electronically coupled superlattices of Cu$_{1.1}$S nanodiscs at the liquid/air interface†

Sonam Maiti, a,b Sanantan Maiti, l,d Andre Maier, b Rupak Banerjee, l,d Chen Shen, d Bridget M. Murphy, e,f Marcus Scheele l,d,b,g and Frank Schreiber b,g

We report on the **in situ** monitoring of the formation of conductive superlattices of Cu$_{1.1}$S nanodiscs via cross-linking with semiconducting cobalt 4,4′,4″,4″′-tetraaminophthalocyanine (CoTAPc) molecules at the liquid/air interface by real-time grazing incidence small angle X-ray scattering (GISAXS). We determine the structure, symmetry and lattice parameters of the superlattices, formed during solvent evaporation and ligand exchange on the self-assembled nanodiscs. Cu$_{1.1}$S nanodiscs self-assemble into a two-dimensional hexagonal superlattice with a minor in-plane contraction (≈ 0.2 nm) in the lattice parameter. A continuous contraction of the superlattice has been observed during ligand exchange, preserving the initial hexagonal symmetry. We estimate a resultant decrement of about 5% in the in-plane lattice parameters. The contraction is attributed to the continuous replacement of the native oleylamine surface ligands with rigid CoTAPc. The successful cross-linking of the nanodiscs is manifested in terms of the high electrical conductivity observed in the superlattices. This finding provides a convenient platform to understand the correlation between the structure and transport of the coupled superstructures of organic and inorganic nanocrystals of anisotropic shape.

Self-assembly of nanocrystals (NCs) into ordered structures has garnered increased attention due to their astonishing properties which are valuable for fundamental studies and technological devices.¹⁻¹² Most of the as-prepared NCs are usually spherical in shape and produce essentially non-conductive superlattices as they feature insulating surface ligands. Recently, little research has been carried out to improve the physical properties of the superlattices by tuning the shape of the NCs, passivating the surfaces of the NCs and cross-linking with organic semiconductor (OSC) molecules.¹³⁻¹⁶ Superstructures of copper sulfide nanomaterials have demonstrated a strong preference to couple between NCs. This might promote high charge carrier transport across the superstructure through resonant energy levels. In spite of the growing importance in the field of fabrication of conductive superstructures by tuning the shape of the NCs, the exact formation mechanism revealing the process is still poorly understood. Here, we use this approach to fabricate a superlattice with interesting transport properties by (a) tuning the shape of the NCs, (b) passivating the NCs’ surfaces, and (c) cross-linking with OSC molecules and following the structure formation in real time.

We choose **in situ** grazing incidence small angle X-ray scattering (GISAXS),¹¹,²⁷,²⁸ which is particularly relevant to elucidating the structure formation in real-time during the involved chemical processes, starting from the self-assembly to ligand exchange. In this context, GISAXS is crucial to determine the **in situ** structural changes in the thin film at the liquid/air interface. We report the **in situ** formation of a conductive hexagonal superlattice of Cu$_{1.1}$S nanodiscs (NDs) by exchanging the native oleylamine (Olm) surface ligand with CoTAPc at the dimethyl sulfoxide (DMSO)/air interface. Initially, the nanodiscs (core diameter 12.7 ± 0.5 nm and thickness 5.8 ± 0.2 nm)

self-assemble into a two-dimensional (2D) hexagonal superlattice after spreading them on the liquid surface with almost unaltered lattice parameters. A continuous contraction of the in-plane lattice parameters occurs during ligand exchange, preserving the 2D hexagonal structure on the liquid surface. The replacement of Olm with CoTAPc ligands in these superlattice films is confirmed by ex situ Raman spectroscopy. A dramatic increase in the conductivity by more than 6 orders of magnitude of the ligand exchanged films suggests that the phthalocyanine derivative acts as an electronic linker between the NDs.

Self-assembly of oleylamine-capped nanodiscs at the DMSO/air interface. Self-assembly of Olm-capped Cu$_{1.1}$S NDs (Fig. S1a, ESI†) has been monitored by dispersing 200 μL, 5 μM NC solution in toluene at the DMSO/air interface in a custom-built Teflon cell with a surface area of 3 x 4 cm$^2$. In situ GISAXS patterns are collected as a function of waiting time at intervals of 4–6 minutes during the self-assembly process. Fig. 1a and b show the GISAXS patterns for waiting periods of 5 minutes and 240 minutes, whereas others at intermediate times are shown in the ESI† (Fig. S2). The appearance of several scattering peaks along the in-plane direction ($q_y$) corresponds to the formation of ordered superlattices. Scattering peaks in the in-plane direction are observed at relative $q_y$-values of 1:\sqrt{3}:2, which is characteristic of a 2D hexagonal superlattice, and are indexed to the (10), (11) and (20) lattice planes, respectively. During the self-assembly process, all the GISAXS patterns show resemblance among themselves, which illustrates that the superlattices remain in a hexagonal geometry for the whole assembling time period. The scattering peaks in the GISAXS patterns are fitted by the distorted wave Born approximation (DWBA)$^{27,29–31}$ method considering a model of a 2D hexagonal superlattice with suitable lattice parameters ($a$, $b$, $c = \text{Inf}$, $\alpha = 90^\circ$, $\beta = 120^\circ$, $\gamma = 0.1^\circ$) and P6mm space group (S.G.) symmetry oriented with the [001]$_{\text{SL}}$-axis perpendicular to the liquid substrate. We found a small contraction in the lattice parameter ($\sim 0.2$ nm) during the first ~40 minutes of self-assembly and almost unaltered $a = b = 16.8 \pm 0.1$ nm for the remaining self-assembly period (until 240 minutes) as shown in Fig. 1c. The obtained lattice parameters also imply that the nanodiscs assemble into a 2D hexagonal superlattice with an edge-to-edge configuration. Fig. 1d shows that the in-plane scattering peaks show no shift in the extracted line profiles of the GISAXS patterns, obtained at different time intervals, except for the first two points (5 and 37 minutes).

Self-assembly of the nanodiscs during ligand exchange at the DMSO/air interface. To gain insight into the ligand exchange process of the self-assembled Cu$_{1.1}$S NDs (already in a 2D hexagonal superlattice) at the DMSO/air interface, we inject a CoTAPc ligand solution into the bulk DMSO and investigate the structural change as a function of reaction time by in situ GISAXS measurements. We recorded a series of GISAXS patterns at regular time intervals of 4–6 minutes during ligand exchange, and Fig. 2a–d presents four selected GISAXS patterns, collected at −42, 6, 24 and 276 minutes, respectively. It should be noted that in the present case the reference time ($t = 0$) is the time of ligand injection into the bulk liquid subphase. During ligand exchange, all the GISAXS patterns of the NDs during self-assembly for waiting periods of (a) 5 min and (b) 240 min. The white circles (transmitted) and red crosses (reflected) are the simulated diffraction patterns considering a 2D hexagonal superlattice. (c) Temporal evolution of the lattice constants. (d) In-plane line profiles along $-q_y$ through the (10) peak of the GISAXS patterns.

exchange, the scattering patterns of all the GISAXS images including the images in the intermediate time periods (Fig. S3, ESf) reveal a high resemblance to the patterns collected during self-assembly (Fig. 1 and 2a). This clearly indicates that the CoTAPc ligands do not significantly change the symmetry of the superlattice during ligand exchange at the liquid/air interface. To determine the transformation of the lattice parameter as a function of reaction time, we again extract the in-plane lattice parameters by simulating and fitting the scattering patterns of each image taking into account DWBA. Additionally, we determine the lattice parameter at different time periods, from the peak position of the corresponding GISAXS line profiles (Fig. 2c) passing through the first correlation peak (−10) along the qy direction.

The patterns correspond to a 2D hexagonal superlattice with P6mm SG symmetry and oriented with the [001]sz axis perpendicular to the liquid surface with varied lattice parameters (Table S1, ESI†). The temporal evolution of the in-plane superlattice parameters (ð) after ligand injection is presented in Fig. 2f. It illustrates that the lattice parameter shrinks almost linearly from 16.75 ± 0.1 to 16 ± 0.1 nm during the time period of 60 min (see Fig. 2f) at a rate of 0.18 Å min⁻¹. For the remaining waiting period (276 minutes), we have not observed any further major contraction of the superlattice. It is important to note that the hexagonal symmetry of the ND superlattices was conserved during the superlattice contraction via ligand exchange with CoTAPc.

Ex situ measurements of the ligand exchanged films. The Raman vibrational spectra of the native and ligand exchanged superlattices are shown in Fig. 3a. The NDs capped with the oleylamine ligand show a sharp peak at 471 cm⁻¹, which can be attributed to the S–S stretching vibration in crystalline CuS nanoparticles (NPs). Several new peaks appearing at 747, 1105, 1336, 1447, 1533 and 1607 cm⁻¹ are due to the presence of CoTAPc in the sample through ligand exchange (red curve in Fig. 3a). These Raman spectra of both are in good agreement with those of the existing literature on crystalline copper sulfide and CoTAPc. In situ synchrotron X-ray scattering to know the formation kinetics of the superlattice during self-assembly of Cu1.1S NDs. We have not observed any similar events even after adding external crosslinking molecules. In our study, we find a very small (~0.2 nm) contraction of the nanocrystal superlattice parameter during self-assembly via solvent evaporation, which is contrary to the solvent evaporation induced assembly of a concentrated solution of spherical PbS NPs (diameter 6.8 nm) at the acetonitrile/air interface. The self-assembly of NCs is attributed to the capillary forces present at the liquid surfaces. On the other hand, this small contraction is consistent with the recent results on cubic PbS NCs (edge length 11.8 nm).12 It has been proposed that the effective capillary forces are not sufficient enough to displace the relatively large size particles.3, 36, 37 We believe that in the present case the small contraction during solvent evaporation is also due to the ineffective capillary forces acting on large diameter (12.7 nm) disc-shaped particles at the air/liquid interface.

In our previous ex situ study (prepared in an inert atmosphere/glove box), we observed that similar NDs organise into hexagonal superlattices for self-assembled (without ligand exchange) and ligand exchanged films with copper 4,4',4",4‴-tetraaminophthaloycyanine (CuTAPc) with similar lattice parameters. In contrast, here we monitored the in situ self-assembly and ligand exchange of similar nanodiscs with CoTAPc as adligands directly at the air/liquid interface using synchrotron X-ray scattering to know the formation kinetics of the structural organization. To understand the effect of structural change on the optoelectronic properties, it is noteworthy to correlate the structural, optical and transport behaviors of the Cu1.1S ND superlattices, formed before and after ligand exchange. While Raman spectra (Fig. 3a, b), particularly the new vibrational peaks above 1000 cm⁻¹, show that the strongly-insulating Olm ligands are replaced by CoTAPc, this removal enhances the current by six orders of magnitude (see Fig. 3b). The significant enhancement in conductivity depicts the efficient charge transport in the coupled superstructures by decreasing the inter-particle separation and increasing electronic coupling among the NDs via semiconducting ligands.
In summary, we have monitored the real time structural evolution of Cu$_{1.1}$S nanodisc superlattices at the DMSO/air interface during self-assembly followed by ligand exchange with CoTAPc molecules. The nanodiscs self-assemble into 2D hexagonal superlattices and their lattice parameters do not change significantly during self-assembly. In contrast, the in-plane lattice parameter of the superlattice contracts isotropically during hexagonal superlattices and their lattice parameters do not interface during self-assembly followed by ligand exchange with CoTAPc molecules. Finally, we demonstrate that the OSC molecules act as electronic coupling agents between the nanodiscs to promote high charge carrier transport across the ordered superlattices.

This work was supported by the DFG under grant SCHE1905/3, SCHE1905/4 and SCHR700/25. We thank the DESY, Hamburg, Germany, for enabling X-ray scattering experiments at P08, Petra-III. We acknowledge the fruitful discussion with F. Bertram, R. Giri and B. Reisz. BMM thanks BMBF for grants 05KS7FK3/05KS10FK2 (LISA spectrometer) and 05K16FK1 (lambda detector). We thank Mrs Nadler for STEM measurements.
